[57] **ABSTRACT**

A drive system for a variable diameter rotor system that includes a plurality of rotor blade assemblies with inner and outer blade segments. The outer blade segment being telescopically mounted to the inner blade segment. The drive system engaging a jackscrew for telescoping the outer blade segment with respect to the inner blade segment. The drive system includes a rotor hub that is pivotally mounted to the upper end of a main rotor shaft about a pivot point. A gimbaled bearing is disposed between and attached to the main rotor shaft and the rotor hub. The gimbaled bearing permits the rotor hub to pivot about the pivot point. A blade actuation shaft is concentrically disposed within the main rotor shaft. The blade actuation shaft has a constant velocity joint pivotally attached to its upper end about the pivot point. A planetary gearset engages the blade actuation shaft with the jackscrew. The planetary gearset includes a sun gear that is attached to the housing and a ring gear that is attached to the rotor hub. A plurality of pinion gears are disposed between and intermesh with the sun gear and the ring gear. The pinion gears are rotatably mounted to a pinion cage which, in turn, is rotatable with respect to the housing and the ring gear. A lower hypoid bevel gear is rotatably driven by the pinion gears and adapted to intermesh with an output pinion on the jackscrew.

## DRIVE SYSTEM FOR A VARIABLE DIAMETER TILT ROTOR

### FIELD OF THE INVENTION

This invention relates to a Variable Diameter Rotor (VDR) system for tilt rotor and/or tilt wing aircraft, and more particularly, to a VDR rotor head assembly for controlling rotation and extension of a plurality of extendable rotor blades.

### BACKGROUND OF THE INVENTION

A tilt rotor or tilt wing aircraft typically employs a pair of rotor systems which are supported at the outermost end of a wing structure and are pivotable such that the rotors may assume a vertical or horizontal orientation. In a horizontal orientation (i.e., horizontal rotor plane), the aircraft is capable of hovering flight, while in a vertical orientation (i.e., vertical rotor plane), the aircraft is propelled in the same manner as conventional propeller-driven fixed-wing aircraft.

Currently, tilt rotor and tilt wing aircraft employ conventional fixed-diameter rotor systems which are aerodynamically and aeroelastically designed in a manner that attempts to blend the competing requirements for hovering and forward flight modes of operation. For example, with regard to hovering flight, it is generally advantageous to employ a large diameter rotor to improve hovering performance by lowering disk loading, reducing noise levels, and reducing downwash velocities. Conversely, a relatively small diameter rotor is desirable in forward flight to improve propulsive efficiency by minimizing blade aero-elastic properties, minimizing blade area, and reducing tip speed (Mach number).

Variable Diameter Rotor (VDR) systems are known to provide distinct advantages over conventional fixed-diameter rotors insofar as such systems are capable of successfully operating in both modes of operation. That is, when the plane of the rotor is oriented horizontally, the rotor diameter is enlarged for improved hovering efficiency and, when oriented vertically, the rotor diameter is reduced for improved propulsive efficiency.

An example of one VDR system and VDR blade assembly is shown in U.S. Pat. No. 3,768,923 which discloses a blade assembly with an outer blade segment configured to telescope over a torque tube member. The size of the rotor diameter is varied by controlling the extension and/or retraction of the outer blade segment. The outer blade segment includes a structural spar which carries the primary loads of the outer blade segment, a leading edge sheath assembly and trailing edge pocket assembly, which sheath and pocket assemblies envelop the spar section to define the requisite aerodynamic blade contour. The torque tube member is mounted to the rotor hub assembly. The spar member of the outer blade segment slides over the torque tube member. In addition to supporting the outer blade segment, the torque tube member functions to transfer flapwise and edgewise bending loads to and from the rotor hub while imparting pitch motion to the outer blade segment.

A retraction/extension mechanism is located within the torque tube member and spar. In one embodiment of the invention, the retraction/extension mechanism includes a threaded jackscrew which may be driven in either direction by a bevel gear arrangement disposed internally of the rotor hub assembly. The jackscrew engages a plurality of stacked nuts which are permitted to translate axially along the jackscrew upon rotation thereof. Centrifugal load straps extend from each nut and are affixed via a retention plate to

the tip end of the spar member. As the jackscrew turns, the stacked nuts are caused to translate inwardly or outwardly, thereby effecting axial translation of the outer blade segment. Systems relating to and/or further describing VDR systems are discussed in U.S. Pat. Nos. 3,884,594, 4,074, 952, 4,007,997, 5,253,979, and 5,655,879.

U.S. Pat. No. 5,299,912 discloses another retraction/extension mechanism for a variable diameter rotor system. The retraction/extension mechanism includes coaxial rotor shafts which are engaged with the rotor blade. More particularly, the outer rotor shaft is attached to a rotor hub through a gimbaled bearing and provides rotational control over the rotor blade. The inner rotor shaft is attached to a bevel gear which, in turn, meshes with a bevel pinion mounted on a jackscrew. The jackscrew is engaged with the outer blade segment as described above. Rotation of the inner shaft produces corresponding rotation of the jackscrew, which extends or retracts the outer blade segment.

The primary drawback of the prior art systems is that they were designed primarily for developmental purposes. Those designs typically did not accommodate the dynamic loads that are produced in full size hardware designs, including gear tooth bending loads, and hertz stress to accommodate the torque load required to operate a driving screw member. The driving screw torque is a direct function of the centrifugal force created by the components of each blade assembly.

A need, therefore, exists for an improved gimbaled rotor head configuration for a variable diameter rotor system.

### SUMMARY OF THE INVENTION

A drive system for a variable diameter rotor system in an aircraft. The variable diameter rotor system including a main rotor shaft and a plurality of rotor blade assemblies with inner and outer blade segments. The outer blade segment being telescopically mounted to the inner blade segment. A jackscrew is rotatably disposed within the rotor blade assembly and engaged with the outer blade segment for telescoping the outer blade segment with respect to the inner blade segment.

The drive system including a rotor hub that is pivotally mounted to the upper end of the main rotor shaft about a pivot point. The pivot point is located at the intersection of the rotor hub axis of rotation and a line along the mass center of the rotor blade assemblies.

First and second elastomeric bearings are disposed between and attached to the main rotor shaft and the rotor hub. The first and second bearings permit the rotor hub to pivot about the pivot point while transmitting rotational loads.

A blade actuation shaft is concentrically disposed within the main rotor shaft. The blade actuation shaft has a constant velocity joint pivotally attached to its upper end about the pivot point.

A planetary gearset is located within the rotor hub and engages the blade actuation shaft with an output pinion formed on the inner end of the jackscrew. The planetary gearset includes a sun gear that is attached to the housing and a fixed ring gear attached to the rotor hub and located radially outboard from the sun gear. A plurality of pinion gears are disposed between and intermesh with the sun gear and the ring gear. The pinion gears are rotatably mounted to a pinion cage which, in turn, is rotatable with respect to the housing and the fixed ring gear. A lower hypoid bevel gear is rotatably driven by the pinion gears and adapted to intermesh with the output pinion on the jackscrew.

The foregoing and other features and advantages of the present invention will become more apparent in light of the following detailed description of the preferred embodiments thereof, as illustrated in the accompanying figures. As will be realized, the invention is capable of modifications in various respects, all without departing from the invention. Accordingly, the drawings and the description are to be regarded as illustrative in nature, and not as restrictive.

### BRIEF DESCRIPTION OF THE DRAWINGS

For the purpose of illustrating the invention, the drawings show a form of the invention which is presently preferred. However, it should be understood that this invention is not limited to the precise arrangements and instrumentalities shown in the drawings.

FIG. 1A is a plan view of a tilt-rotor aircraft illustrating the variable diameter rotor system according to the present invention in its horizontal position.

FIG. 1B is a front view of a tilt-rotor aircraft illustrating the variable diameter rotor system according to the present invention in its vertical position.

FIG. 2 is a cross-sectional side view of one embodiment of the variable diameter rotor system according to the present invention.

FIG. 3 is a cross-sectional top view of the variable diameter rotor system of FIG. 2.

FIG. 4 is a schematic representation of retraction/extension actuation system for controlling retraction and extension of a variable diameter rotor blade.

FIG. 5 is a graphical depiction of an engagement profile for use in the retraction/extension actuation system shown in FIG. 4.

FIG. 6A is a cross-sectional view of a linear constant velocity joint suitable for use in the present invention.

FIG. 6B is a cross-sectional view of the linear constant velocity joint of FIG. 6A taken along lines 6B—6B.

FIG. 7 is a cross-sectional side view of an alternate rotor hub assembly according to the present invention.

FIG. 8 is a cross-sectional view taken along lines 8—8 in FIG. 7.

### DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Referring now to the drawings, wherein like reference numerals illustrate corresponding or similar elements throughout the several views, FIGS. 1A and 1B illustrate a tilt rotor aircraft that includes a pair of variable diameter rotor (VDR) systems 10 according to the present invention. The VDR systems 10 are shown pivotally mounted on laterally extending wing sections 12 of the aircraft. The VDR systems 10 are pivotable between a horizontal or hover flight position, shown in FIG. 1A, and a vertical or forward flight position, shown in FIG. 1B.

Each VDR system 10 includes a plurality of variable diameter rotor blade assemblies 14 which are capable of being extended and retracted to vary the size of the rotor diameter RD as needed. More particularly, in order to provide the maximum vertical lift for the aircraft, it is desirable to increase the size of the rotor diameter RD by extending the rotor blade assemblies 14. Conversely, in forward flight it is generally more desirable to shorten the rotor diameter RD by retracting the rotor blade assemblies 14.

In order to effectuate the change in diameter, the variable diameter rotor blade assemblies 14 include a torque tube

member 16 and an outer blade segment 18 which telescopes over the torque tube member 16. The general structure of one suitable variable diameter rotor blade assembly 14 for use in the present invention is disclosed in U.S. Pats. Nos. 5,655,879 and 5,636,969, the disclosures of which are incorporated herein by reference in their entirety.

The variable diameter rotor system 10 also includes a rotor hub assembly 20 to which the rotor blade assemblies 14 are mounted. Referring to FIG. 2, a cross-sectional view of the variable diameter rotor system 10 is shown illustrating the rotor hub assembly 20 in more detail. The rotor hub assembly 20 is mounted to a main rotor shaft 22 which is operative for rotatably driving the rotor hub assembly 20 (and rotor blade assemblies 14) about a rotational axis 24. The main rotor shaft 22 is conventional in the art and, thus, no further discussion is needed. The main rotor shaft 22 is attached to a transmission (not shown) which rotates the main rotor shaft in a prescribed direction and at a suitable speed.

The main rotor shaft 22 is attached to the rotor blade assemblies 14 through a gimbaled bearing 26 arrangement. The gimbaled bearing 26 transmits rotor thrust loads to the main rotor shaft and permits the hub assembly 20 to have limited angular (pivotal) movement with respect to the main rotor shaft 22. The gimbaled bearing 26 provides the ability to tilt the rotor plane relative to the main rotor shaft 22 centerline resulting in a thrust vector that is used to maneuver the aircraft in the helicopter mode. The gimbaled pivot bearing 26 also provides reduced blade root stresses resulting from out of plane blade flapping motion that occurs from rotor cyclic and vertical gust inputs. The gimbaled bearing 26 includes a lower bearing support 28 which is engaged with an upper portion of the main rotor shaft 22. Any conventional method for attaching the lower bearing support 28 to the main rotor shaft 22 can be used such that rotary motion can be transmitted therebetween. In one preferred embodiment, the engagement between the lower bearing support 28 and the main rotor shaft 22 is provided by a splined connection. The lower bearing support 28 surrounds at least a portion of the upper end of the main rotor shaft 22 and includes a lower bearing surface 30 which is preferably substantially hemispherical in shape.

A first elastomeric thrust bearing 32 is located adjacent to the lower bearing surface 30. Elastomeric bearings are well known in the art and generally comprise alternating layers of elastomer and nonresilient shims. See, for example, U.S. Pat. No. 4,203,708. The number of elastomer layers and shims is not limited to the number shown in the figures but, instead, would be determined by the applied rotor loads. The first elastomeric bearing 32 is preferably hemispherical in shape and located substantially concentric with the rotor hub assembly 20 so as to be rotatable about the rotational axis 24. A lower bearing member 34 is disposed about and in contact with the outer surface of the first elastomeric bearing 32, so as to sandwich the first elastomeric bearing 32 between the lower bearing member 34 and the lower bearing surface 30. The lower bearing member 34 is attached to a rotor hub 39 for transmitting rotational motion therebetween.

The gimbaled bearing 26 also includes an upper bearing support 36 which is attached to the lower bearing support 28 through any conventional means, such as a bolt. The upper bearing support 36 includes an upper bearing surface 38 which, in one embodiment, is preferably continuous about the rotational axis 24 and has a center of rotation which is substantially co-linear with the rotational axis 24. A second elastomeric preload bearing 40 is disposed on the upper bearing surface 38. The second elastomeric bearing 40 is

constructed similar to the first elastomeric bearing 32. The second elastomeric bearing 40 is mounted so as to provide preloading of the bearing assembly 26. The preload is preferably equal to the rotor thrust load plus 1.5 g's. The preload is sized such that when the maximum thrust load is applied to the first elastomeric bearing 32, no tensile stresses (i.e., complete loss of compression load) results in the second elastomeric bearing 40.

An upper bearing member 42 is disposed on the outer surface of the second elastomeric bearing 40. As such, the second elastomeric bearing 40 is sandwiched between the upper bearing member 42 and the upper bearing surface 38. The upper bearing member 42 is attached to the hub 39. A torque link 43 connects the upper bearing support 36 to the upper bearing member 42.

In the illustrated embodiment, the elastomeric spherical bearings 32, 40 are not permitted to transmit torque since the application of torque would reduce the angular capacity of the bearings. Instead, the present invention transmits drive torque around the spherical bearings by using a link-type rotary coupling (constant velocity joint), similar to the rotary coupling shown in U.S. Pat. No. 4,804,352, which is incorporated herein by reference in its entirety. The rotary coupling 50 is shown in greater detail in FIGS. 6A and 6B and will be discussed in more detail below. The elastomeric bearings 32, 40 are mounted so as to permit limited pivoting of the rotor head assembly 20 about a pivot center 44 which is located at the intersection of the rotational axis 24 and the longitudinal pitch axis 46 of the rotor blade as shown in FIG. 3. That is, the elastomeric bearings 32, 40 are each preferably formed with a hemispherical shape and have a common center of curvature. The center of curvature defines the point about which the rotor hub assembly can pivot with the least amount of out-of-plane loading (i.e., the pivot center).

The gimbaled arrangement shown in the figures and discussed above permits approximately 12° of pivotable motion. The 12° of motion allows the rotor head to vary the orientation of the rotor plane from its normal or true horizontal plane allowing thrust in the horizontal plane when the aircraft is in the helicopter or vertical mode of flight.

In order to control extension and retraction of the outer blade segment 18, the present invention includes a second drive shaft. As shown in FIG. 2, the second drive shaft or blade actuation shaft 48 is preferably located within the main rotor shaft 22. More particularly, the blade actuation shaft 48 is preferably mounted concentrically within and rotatable with respect to the main rotor shaft 22. The blade actuation shaft 48 is engaged with a suitable actuation system so as to be rotatable relative to the main rotor shaft 22.

Since the rotor hub assembly is gimbaled, the attachment between the blade actuation shaft 48 and the rotor blade assemblies 14 must be designed to accommodate up to 12° of rotor hub pivoting, as well as vertical displacement caused by the thrust of the rotor. These thrust loads must be isolated from the blade actuation shaft 48. The incorporation of a linear constant velocity joint 50 in the present invention at the elastomeric bearing pivot center provides the required isolation.

Referring to FIGS. 2, 6A and 6B, the linear constant velocity joint 50 is used to couple the blade actuation shaft 48 to the rotor blade assemblies 14. The constant velocity joint 50 is designed to transmit torque from the blade actuation shaft 48 to the rotor blade assemblies 14, while permitting axial and pivotal motion of the rotor hub assembly 20. In one embodiment of the invention, the constant

velocity joint 50 includes an output housing 52 and an input assembly 200. The input assembly 200 is connected to the blade actuation shaft 48 through a splined connection 202. The input assembly 200 includes a tri-lobed trunnion 204 with needle bearing rollers 206 rotatably mounted around each trunnion 204. The outer race on the needle bearing rollers 206 is in rolling contact with the inner surface of the outer housing 52. As such, the coupling 50 transmits torsional input to the output housing 52 while permitting low frictional axial (vertical) displacement of the housing 52 with respect to the trunnion inner assembly 200.

As shown in FIG. 2, the housing 52 is preferably supported by a cap member 54 that is mounted to the hub 39. More particularly, at least one roller bearing 56 is located between the housing 52 and a cylindrical flange 58 extending downward from the cap member 54. Thus, the housing 52 is free to rotate with respect to the cap member 54.

A sun gear 60 is formed on a portion of the housing 52. While in the illustrated embodiment the sun gear 60 is shown as being integral with the housing 52, it is also contemplated that the sun gear 60 can be a separate gear that is attached to the housing 52. The sun gear 60 is preferably made from a high strength material, such as steel.

In order to use the rotary motion of the sun gear 60 to extend and retract the outer blade segments 18, the present invention incorporates a single stage planetary geartrain into the rotor hub assembly 20. The single stage planetary provides two functions. First, the single stage planetary reduces the actuation shaft 48 torque loads to a realistic operating value. Second, the compound planetary provides a predetermined travel time for the blade extension and retraction motion. The blade travel is a direct function of the actuation power source speed and the related gearing associated with the drive mechanism and the system actuation control unit.

Referring to FIGS. 2 and 3, the sun gear 60 provides input to the single stage planetary geartrain. In one embodiment, the planetary geartrain includes a pinion cage or support 70 which rotatably supports a plurality of pinion gears 62. The pinion gears 62 are disposed between and engage with the sun gear 60 and a ring gear 68. The ring gear 68 is located radially outward from the pinion gears 62 and is attached to the rotor hub 39 through any conventional means, such as a bolted attachment. The pinion gears 62 or the pinion cage 70 are interconnected with a hypoid bevel gear 76. More particularly, in the embodiment of the invention shown in FIG. 2, the hypoid bevel gear 76 is fixedly attached to the pinion cage 70 so as to be rotatable therewith about the rotational axis 24. The hypoid bevel gear 76 interacts with an output bevel pinion gear 78.

The intermeshing of the pinion gear 62 with the grounded ring gear 68 results in the desired rotational motion of the pinion cage 70 and the related hypoid bevel gear 76. The ring gear 68 and the pinion gears 62 are preferably both made from steel. In one embodiment of the invention, the intermeshing of the ring gear 68 and the pinion gears 62 provides about a 2.58:1 gear reduction and the single stage planetary gearset produces an overall gear ratio of 6:20:1. If desired, a compound planetary gear set may be configured to provide a gear ratio of 13:1 if additional reduction in applied torque and speed is required.

As shown in the illustrated embodiment, the pinion gears 62 are each rotatably mounted to the pinion cage 70 through a roller bearing 72. The pinion cage 70 is, in turn, in contact with and rotatably supported by the hub 39 through a roller assembly 74. Any conventional roller assembly 74 can be

used to support the pinion cage **70**. The lower hypoid bevel gear **76** is formed on the pinion cage **70** and defines a ring within the rotor hub assembly **20**. The lower hypoid bevel gear **76** can be integral with the pinion cage **70**, or may be separately bolted to the support as is illustrated. The lower hypoid bevel gear **76** meshes with the output pinion **78**. As will be discussed in more detail below, the output pinion **78** is attached to the outer blade portion **18**. The teeth on the lower hypoid bevel gear **76** and the output pinion **78** are formed so as to result in an intermeshing between the two gears along a line that intersects with the blade pitch pivot centerline **66** of the rotor blade **18** as shown in FIG. 3. The blade pitch centerline **66** is offset from the pivot center **44**. The output pinion **78** is located within the main rotor hub assembly **20** and, thus, allows the rotor hub to achieve upwards of 12 degrees of pivotal motion with the gear mesh tracking with it. The intermeshing between the lower hypoid bevel gear **76** and the output pinion **78** defines a lower bevel stage of the planetary gear. The lower hypoid bevel gear **76** and the output pinion **78** are both preferably made from steel. In one embodiment of the invention, the meshing between the two gears provides a gear reduction of about 3.58:1.

As shown, roller bearings **80** permit the output pinion **78** to freely rotate about its rotational axis within the hub **39**. The output pinion **78** is attached to a drive shaft **82** preferably through a splined connection. The drive shaft **82** preferably includes crowned splines that are capable of accommodating misalignment resulting from motion of the jackscrew **84** relative to its support bearing **86**. In one embodiment of the invention, the quill shaft could include a disk type misalignment coupling identified in FIG. 2 by the numeral **83**. One suitable disk coupling **83** is a Lucas coupling sold by Lucas Co., of Utica, N.Y. The jackscrew **84** is rotatably mounted within the rotor hub **39** and torque tube member **16**.

Since in-plane and out-of-plane motions occur on the rotor blade **18**, a flexible elastomeric bearing support **86** is preferably incorporated between the jackscrew **84** and the rotor hub **39** to reduce the effective bending loads applied to the jackscrew **84**. More particularly, a hemispherical bearing **87** is located between a complimentary screw support **88** and hub support **89**. The screw support **88** is rotatably disposed about the jackscrew **84**. The hub support **89** is attached to the hub **39** through any conventional means known to those skilled in the art. The jackscrew **84** is preferably attached to the outer blade segment **18** through any conventional means, such as the attachment disclosed in U.S. Pat. No. 5,636,969.

The above described design of the present invention, with the planetary gear set positioned above and to the sides of the gimbaled bearing **26**, allows the entire rotor hub assembly **20** to be easily removed from the main rotor shaft **22**, thus facilitating maintenance and repair.

In order to more clearly understand the extension and retraction mechanism of the present invention, a brief discussion of the rotor systems' operation will now be provided. Starting with the variable diameter rotor blade assemblies **14** in their retracted position. The main rotor shaft **22** is rotated as is conventional in the art (i.e., the transmission rotates the main rotor shaft **22**). For the illustrated aircraft configuration, a control mechanism is located in relation to the main rotor shaft such that power to operate the extension/retraction mechanism is derived from the main rotor shaft **22** at 250 RPMs and results in the rotation of the blade actuation shaft **48**. This results in approximately 500 foot-pounds of torque input to the blade actuation shaft **48**. When commanded, the blade extension/retraction control mecha-

nism produces rotational forward and reverse output of the blade actuation shaft **48** relative to the main rotor shaft **22** at approximately 3144 RPMs. With the planetary gearset ratio of 6:20:1 and the hypoid gearset ratio of 3.58:1, the resulting jackscrew **84** rotational speed is approximately 872 RPMs.

In the non-operating modes, i.e., fully extended or fully retracted, the blade actuation shaft **48** is not rotating relative to the main rotor shaft **22**, but is rotating at the same speed (250 RPMs) as the main rotor shaft **22**. The blade actuation shaft **48** rotates the housing **52** of the constant velocity joint **50**. This results in the sun gear **60** rotating about its rotational axis (which, when there is no deflection of the rotor hub assembly **20**, coincides with the rotational axis **24** of the main rotor shaft **22** and the blade actuation shaft **48**). The sun gear **60**, in turn, rotates the pinion gears **62**. Accordingly, the pinion gears **62** simply rotate about their rotational axis **62A** while, at the same time, transitioning around the rotor hub assembly **20** at the same speed as the main rotor shaft **22**.

When it is desired to extend the outer blade segment **18** of the rotor blade assembly **14**, the blade actuation shaft **48** must be controlled so as to rotate at a speed that is relative to the main rotor shaft **22**. This relative motion is either in the forward or reverse direction. The gearing in one embodiment of the invention is sized such that the relative speed of the blade actuation shaft **48** with respect to the main rotor shaft **22** in forward (extension) and reverse (retraction) directions is substantially the same. It must be noted that, since the retraction/extension mechanism is installed relative to the main transmission housing, the output speeds are determined relative to the 250 RPMs of the main rotor shaft **22** speed.

In the exemplary planetary gearset discussed above, the jackscrew **84** rotates at about 872 RPMs and at approximately 350 foot-pounds is limited by the maximum centrifugal force in the blade extended position, the jackscrew lead, and the efficiency of the jackscrew nut for each blade. This results in the outer blade segment **18** transitioning through a full 110 inches of extension in about 15 seconds.

Retraction of the outer blade segment **18** is accomplished by rotating the blade actuation shaft **48** again at a speed that is relative to the speed of the main rotor shaft **22** but in the opposite direction from extension.

FIG. 7 illustrates an alternate rotor hub assembly **400**. Many features of this assembly **400** as the same as the prior assembly discussed in detail above. As such, only the primary components that are different from the prior assembly are discussed hereinafter. The rotor hub assembly **400** includes a gimbaled bearing arrangement **402** which attaches the main rotor shaft **22** to the rotor blade assemblies **14**. As with the prior arrangement, the gimbaled bearing **402** transmits rotor thrust loads to the main rotor shaft **22** while permitting the hub assembly **400** to have limited angular movement.

The gimbaled bearing **402** includes a lower bearing support **404** which is attached to the main rotor shaft **22**. A first elastomeric preload bearing **406** is located between the lower bearing support **404** and a lower surface of a blade bearing mount **408**. A second elastomeric thrust bearing **410** is located between an upper surface on the blade bearing mount **408** and an upper bearing support **412**. The upper bearing support is attached to the main rotor shaft **22** though any conventional mounting arrangement, such as the illustrated splined connection. The blade bearing mount **408** is fixedly attached to the rotor blade hub **39**. A torque link **409** connects the blade bearing mount **408** to the upper bearing support **412** as shown in FIG. 8.

One common misconception in the prior art was that in order to provide proper pivoting of the rotor hub, the gimbaled bearings had to be arranged with their pivot center located on the center line of the rotor blade assembly. The primary deficiency with this mounting arrangement is that the blade typically has a pre-cone. As such, the center of mass of the blade does not typically lie along the center line of the rotor blade. Accordingly, the blade in these prior art arrangements would tend to droop when the aircraft was not in use, resulting in undesirable loading on the bearing from out-of-plane runout during start-up of the rotor. In one embodiment of the invention, this problem is alleviated by mounting the elastomeric bearings **32**, **40** with their pivot center located at the intersection of the rotational axis **24** and a horizontal plane passing through the mass center of the rotor blade assembly **14**. Since conventional rotor assemblies, such as the rotor assembly shown in FIG. **7**, are designed with a "pre-cone", the mass center of the rotor blade assembly **14** will be located above the point where the pitch axis centerline **46** intersects the rotational axis **24**. For example, in the rotor hub assembly **20** shown in FIG. **7**, the pivot center **44** is located approximately 4.5 inches above the intersection of the blade pitch axis **46** with the rotational axis **24** (identified as D).

As discussed previously, the blade actuation shaft **48** is engaged to a planetary gearset through a liner constant velocity joint **50**. As shown in this alternate embodiment, the outer housing **52** of the constant velocity joint **50** has a sun gear **414** formed on it. The sun gear **414** meshes with a pinion gear **416** that is rotatably supported by a pinion cage **418**. The pinion cage **418**, in turn, is rotatably supported by the outer housing **52** through a roller arrangement. The pinion gear **416** also meshes with a movable ring gear **420**. The movable ring gear is disposed about the pinion cage **418** and is rotatably engaged with the rotor hub **39**.

A lower hypoid pinion gear **76** is attached to or formed on the movable ring gear **420** and drivingly engages with the output pinion **78** for rotating the jackscrew **84** as discussed in the prior arrangement.

A fixed ring gear **422** is attached to the rotor hub **39** and meshes with a secondary pinion **424** that is splined to the pinion gear **416** so as to be rotatable in combination therewith.

The operation of the geartrain shown in FIGS. **7** and **8** will now be briefly discussed. The illustrated geartrain is a compound planetary version which allows for higher reduction ratios than can be achieved with a basic single stage.

The compound planetary in this embodiment utilizes a double pinion arrangement and two ring gears. The input from the sun gear **414** rotates the first stage pinion gear **416** that is interconnected with a second stage pinion gear **424**. The multiple pinions located on the pinion housing/cage **418** rotate around the input sun gear **414**. The output is taken from the first stage ring gear **420** which is driven by the first stage pinions **416**. The ring gear **420** is mechanically attached to the hypoid bevel gear **76**. The rotational output of the planetary system is the result of the interaction of the second stage pinion **424** through the second stage ring gear **422** that is grounded to the rotor housing **39**. In one embodiment of the invention, the planetary geartrain provides a reduction ratio of approximately 13:1.

The rotational sense of the planetary system is such that for either blade extension or retraction, all of the basic components rotate in the same direction. As in the description of the previously described embodiment, the actuation is derived from the rotation of the main rotor shaft which

rotates at 250 RPMs. An input rotation of the main rotor shaft **22** and the interconnected sun gear **414** causes a rotation of the double pinion that is opposite in sense. The cage housing **418** however rotates in the same sense as the sun gear **414**. This rotational speed and direction is determined by the relative size of the gears in the planetary set. The relationship of the larger first stage pinion **416** and the smaller second stage pinion gear **424**, that is reacting with the second stage ring gear **420**, results in a rotational sense of the ring gear **420** that is in the same direction as the input sun gear **414**, but at a speed relative to the reduction ratio speed of the planetary. Rotation of the ring gear **420** produces rotation of the output pinion **78**.

In order to reduce the loading on the extension/retraction mechanism and, in particular, on the straps used to attach the outer blade segment **18** to the torque tube member **16**, the present invention contemplates the incorporation of a locking mechanism **90** into the rotor blade assembly **14**. The locking mechanism preferably locks the outer blade segment **18** to the torque tube and/or rotor hub **39** when the outer blade segment **18** is fully retracted. This eliminates the centrifugal loading that would otherwise be on the extension/retraction mechanism. In one embodiment of the invention, the locking mechanism **90** is a pin or breech type locking device. More particularly, upper and lower locking pins **92** are mounted to corresponding actuators **94** which, in turn, are supported by flanges on the hub or blade root. The locking pins **92** are mounted so as to engage with holes (not shown) formed in the outer blade segment **18** when the outer blade segment **18** is in its fully retracted position.

The benefits obtained from the present invention over prior art systems include the ability to provide controlled rates of the retraction or extension times for the outer blade segment **18** at a predetermined blade actuation shaft maximum input torque. The invention also provides a means for transmitting the operating torque through the angular displacement of a gimbaled rotor head while accommodating the axial displacement in the elastomeric gimbal bearing due to thrust loads.

Referring now to FIG. **4**, a schematic diagram is shown depicting an embodiment of a preferred retraction/extension actuation system **100** for controlling the rotational speed of the blade actuation shaft **48** and, thus, the extension and retraction of the outer blade segment **18**. The retraction/extension actuation system **100** is preferably mounted at or near the lower ends of the main rotor shaft **22** and the blade actuation shaft **48**. The retraction/extension actuation system **100** provides approximately 300 HP (i. e., 100 HP per rotor blade) to control extension and retraction of the rotor system **10**.

The retraction/extension actuation system **100** includes a bevel drive gear **102** which is shown disposed about and splined to the main rotor shaft **22** so as to be rotatable in combination therewith. The bevel drive gear **102** has a set of primary teeth **104** which mesh with mating teeth on an input gear **106** in a primary retraction/extension drive unit **108**. The input gear **106** is engaged with a first or master clutch **110** which controls the engagement between the input gear **106** and a main drive **112**. The main drive **112**, in turn, is engaged with a fixed mount **114** via a disk brake **116**. The brake **116** is actuated during blade extension as will be discussed in more detail below. The main drive **112** engages a forward fixed sun gear planetary gearset **124** and with a reverse fixed pinion planetary gearset **118**.

A forward clutch **122** controls engagement between the main drive **112** and a forward planetary gearset **124**. The

forward planetary gearset **124** is defined as a fixed sun, single stage planetary which includes multiple pinions **125**, an outer ring gear **126**, and an inner sun gear **127**. The forward clutch **122** is interconnected to the cage of the multiple pinions **125**. The sun gear is interconnected to ground **120** through a cage of multiple pinions **121** on the reverse fixed pinion gearset **118**. When the forward clutch **122** is engaged, the pinions **125** of the forward planetary gearset **124** rotate about the sun gear **127** resulting in rotation of the outer ring gear **126** in the forward direction. The outer ring gear **126** is interconnected through an output shaft **128** to output pinion **132**.

The reverse planetary **118** is defined as a fixed pinion, single stage planetary which includes multiple pinions **121**, an outer ring gear **129**, and an inner sun gear **123**. The input of a reverse clutch **130** is interconnected to the sun gear **123** and the output is interconnected to the output shaft **128**. When the reverse clutch **130** is engaged, rotational input from the main drive **112** rotates the outer ring gear **129**. The fixed or grounded cage of pinions **121** causes the sun gear **123** to rotate in the opposite direction, thereby resulting in reverse rotation of the output shaft **128**.

The output drive **128** is coupled to an output bevel gear **132** which, in turn, is engaged with a primary set of teeth **133** on a blade actuation drive gear **134** formed on the blade actuation shaft **48**.

A rotor blade actuation control unit **136** controls the engagement between the various clutches and the brake **116** in the primary retraction/extension drive unit **108**. In one preferred embodiment of the invention, the actuation control unit **136** controls the actuation cycle by regulating engagement of one or more of the clutches and brake **116** according to a profile. More particularly, referring to FIG. 5, a preprogrammed profile is shown for controlling actuation of the extension/retraction drive unit **108**. The profile includes a ramp-up in operational speed that lasts for approximately 2–3 seconds. More particularly, during the ramp-up, the engagement between the master clutch **110** and the main drive **112** is allowed to slip until fully engaged. Similarly, there is a ramp down in operational speed when it is desired to disengage the clutches. The ramp-down also lasts for approximately 2–3 seconds, during which time the master clutch **110** is permitted to slip while operating in conjunction with brake **116**. This cooperation of the master clutch **110** and brake **116** occurs during a blade extend cycle operation. During a blade extend cycle, the forward clutch **122** and the master clutch **110** are engaged. At the point of ramp-down, the forward clutch **122** is disengaged and modulated application of the brake **116** occurs with modulated disengagement of the master clutch **110** to ease the outer blade segment into its completely extended position. The engagement profile with its ramp-up and ramp-down portions helps to reduce the high load spike that would otherwise result in the system.

It is also contemplated that the rotor blade control unit **136** will monitor the blade operating system condition parameters to determine the overall health status of the rotor system. For example, the rotor blade control unit **136** may receive signals representing blade position, actuating oil pressure, and oil temperature. From this information a “go/no-go” decision can be made by the control unit **136**. Additionally, the monitored information can be used to adjust the profile if needed. For example, the actual blade position can be monitored to adjust when the ramp-up and ramp-down occurs.

It is also contemplated that a secondary retraction/extension drive unit **140** may be incorporated into the

system to provide redundancy in case of a failure in the primary drive unit. It is further contemplated that the secondary retraction/extension drive unit **140** can be designed to engage with a set of secondary teeth **142** located adjacent to the drive gear **102**. Similarly, the output bevel gear in the secondary retraction/extension drive unit **140** can be configured to engage with secondary set of teeth **144** on a blade actuation shaft drive gear **134**. The use of primary and secondary sets of teeth on the drive gear **102** and the blade actuation drive gear **134** is intended to provide redundancy in the system. If redundancy is not a concern, only one set of teeth on each gear would be required.

As shown in FIG. 4, the gearing arrangement in the secondary retraction/extension drive unit **140** is substantially the same as the gearing arrangement in the primary retraction/extension drive unit **108**. Hence, no further discussion is needed. As with the primary retraction/extension drive unit **108**, the secondary retraction/extension drive unit **140** is controlled by the rotor blade retraction/extension control unit **136**.

The retraction/extension actuation system **100** is preferably arranged with the clutches oriented vertically as shown. This alleviates any pressure differentials and/or gyroscopic loads that might otherwise develop if the unit incorporated horizontally oriented clutches. The clutches and brakes that are used in the present invention are preferably an oil type that will have nearly identical static and dynamic coefficients of friction. In addition to the beneficial coefficient of friction, oil or wet type clutches and brakes also have better improved lubrication, and system health monitoring capability over dry type devices.

It is desirable that a gear ratio of 2:1 exist between the drive gear **102** and the input gear **106**. It is also desirable that a gear ratio of 2:2 exist between the output bevel gear **132** and the blade actuation shaft **48**.

The retraction/extension actuation system **100** also preferably includes a brake unit **146** which is used to lock the main rotor shaft **22** to the blade actuation shaft **48**. The rotor blade control unit **136** preferably controls engagement of the brake unit **146**. By allowing the rotor shafts to be locked into engagement, it is possible to unload (disengage) the primary drive unit **108** or secondary drive unit **140**. The application of this function is desirable in the event of a detected malfunction in either the primary drive unit **108** or the secondary drive unit **140** during operation, allowing the system to lock in a fixed portion. Braking systems are well known in the art. See, for example, U.S. Pat. No. 5,299,912, the disclosure of which is incorporated herein by reference in its entirety.

The operation of the retraction/extension actuation system **100** will now be discussed. When the variable diameter rotor blade assembly **14** is in its retracted position (i.e., with the outer blade segment fully retracted), the main rotor shaft **22** and the blade actuation shaft **48** will be rotating concurrently at the same speed and in the same direction. The input gear **106** is in constant engagement with the main rotor shaft bevel gear **102** through the bevel gear mesh **104**. Consequently the input gear **106** rotates at a constant 500 RPMs.

To initiate an extension or a retraction operation, the rotor blade retraction/extension control unit **136** commands engagement of the appropriate clutch (e.g., forward clutch **122**) in the drive unit **108** and then the master clutch **110**. The rotor blade retraction/extension control unit **136** sequences the engagement of the master clutch **110** and brake **116** to achieve the desired profile as shown in FIG. 5. At the completion of the retraction or extension operation, the drive unit **108** is disengaged.

When the blade is fully retracted or extended, the blade extension mechanism must be restrained or locked so that the blade actuation shaft **48** can once again rotate at the same speed and in the same direction as the main rotor shaft **22**. There are two methods for achieving this in the illustrated embodiment. First, the brake **146** can be applied to lock the shafts together. However, a more preferred method is to use the blade locking mechanism **90** to lock the outer blade segment. As discussed above and shown in FIG. 2, the blade locking mechanism **90** locks the outer blade segment to the blade root or hub **39** when the blade is in its retracted position. In order to unload the blade extension mechanism **100** when the blades are in the extended position, internal stops (not shown) are incorporated in the blades. The outer blade segment **18** contacts the stops when it reaches the fully extended position and the rotor blade's centrifugal force maintains blade in the extended position. The unloading of the blade extension/retraction mechanism **100** minimizes fatigue loading.

In order to initiate a blade extension from the retracted position with the blade locking mechanism **90**, the centrifugal load must first be relieved in order to disengage the locking device. To accomplish this, the rotor blade/extension control unit **136** first initiates a blade retraction operation to "pull-in" the blades to relieve the centrifugal load on the blade locking mechanisms **90**. This retraction sequence utilizes the same clutches and the brake used for the normal retraction operation, however the cycle will not follow the operation profile. More particularly, first the reverse (retract) clutch **130** is engaged, followed by the master clutch **110** to relieve the blade centrifugal load. At this point, the position brake **146** is engaged and the locking mechanisms **90** are disengaged (as determined by sensors). The forward (extend) clutch **122** is then engaged with the subsequent engagement of the master clutch **110** and the concurrent controlled release of the position brake **146**.

The outer blade segments **18** extend in accordance with the normal operation profile shown in FIG. 5. At the 2-3 second ramp-down point, the application of brake **116** is controlled with the concurrent release of the master clutch **110**, easing the blade onto the position stops.

When it is desired to retract the outer blade segment **18**, the rotor blade control unit **136** initiates the following sequence of events. The reverse (retract) clutch **130** is engaged and then a controlled slip engagement of the master clutch **110** occurs to meet the 2-3 second "ramp-up" profile as defined in FIG. 5. As the outer blade segments **18** approach the retracted stop position, the rotor blade control unit **136** commands a controlled slip of the master clutch **110** to meet the "rampdown" profile specified in FIG. 5. At the point of engagement with retract position stops, the brake **146** engages and the blade locking mechanisms **90** are engaged. After the lock position sensors signal completion of the lock engagement sequence, the brake **146** is controlled to ease the centrifugal load onto the locks.

The above retraction/extension system **100** provides a novel mechanism for controlling the extension and retraction of a variable diameter rotor blade, such as the exemplary embodiment provided in this specification. The choice of gear set ratios in the retraction/extension system **100** may be selected to accommodate various rates of retraction or extension.

Although the invention has been described and illustrated with respect to the exemplary embodiments thereof, it should be understood by those skilled in the art that the foregoing and various other changes, omissions and addi-

tions may be made therein and thereto, without parting from the spirit and scope of the present invention.

What is claimed is:

1. A gimbaled rotor hub assembly for a variable diameter rotor system, the system including a plurality of rotor blade assemblies mounted to and rotated by the rotor hub assembly about an axis of rotation, each rotor blade assembly having an inboard blade section and an outboard blade section, the outboard blade section being telescopically mounted to the inboard blade section, each rotor blade assembly having a mass center, the system further including a jackscrew rotatably disposed within the rotor blade assembly and engaged with the outboard blade section for telescoping the outboard blade section with respect to the inboard blade section, the jackscrew having an output pinion located at its inboard end, the gimbaled rotor hub assembly comprising:

- a main rotor shaft having an upper end;
- a rotor hub disposed about the upper end of the main rotor shaft, the blade assemblies being spaced about and attached to the rotor hub;
- a gimbaled bearing disposed between and engaged with the main rotor shaft and the rotor hub, the gimbaled bearing including first and second elastomeric bearings, each having a partial substantially spherical shape with a substantially common pivot center, the pivot center being located substantially in line with the mass center of the rotor blade assemblies;
- a blade actuation shaft concentrically disposed within the main rotor shaft, the blade actuation shaft having an upper end;
- a linear constant velocity joint movably attached to the upper end of the blade actuation shaft, the constant velocity joint having a housing that is rotatably supported by the rotor hub; and
- a planetary gearset located within the rotor hub assembly including
  - a sun gear attached to the housing,
  - a plurality of pinion gears disposed about and intermeshing with the sun gear, the pinion gears being rotatably mounted to a pinion cage, the pinion cage being rotatable with respect to the rotor hub and the housing,
  - a lower hypoid bevel gear rotatably driven by the pinion gears, the lower hypoid gear forming a ring within the rotor hub assembly, the lower hypoid bevel gear adapted to intermesh with the output pinion on the jackscrew, and
  - a first ring gear located radially outward from and intermeshing with the pinion gears.

2. A gimbaled rotor hub assembly according to claim 1 wherein the pivot center is located above the first elastomeric bearing and below the second elastomeric bearing, the rotor hub assembly further comprising a bearing support attached to the main rotor hub, and upper and lower bearing members attached to the rotor hub, wherein the first elastomeric bearing is sandwiched between the bearing support and the lower bearing member and the second elastomeric bearing is sandwiched between the bearing support and the upper bearing member.

3. A gimbaled rotor hub assembly according to claim 1 wherein the first and second elastomeric bearings include a plurality of elastomer layers interleaved with nonresilient shims.

4. A gimbaled rotor hub assembly according to claim 1 wherein the planetary gearset includes a movable ring gear

## 15

which is intermeshed with the pinion gears, the lower hypoid bevel gear being fixedly attached to the movable ring gear, the pinion cage being rotatably supported by the outer housing, and wherein the first ring gear is fixedly attached to the rotor hub and meshes with a secondary pinion that is splined to the pinion gear.

5. A gimbaled rotor hub assembly according to claim 1 wherein the lower hypoid bevel gear is fixedly engaged with pinion cage such that rotation of the pinion cage by the pinions causes the lower hypoid bevel gear to rotate.

6. A gimbaled rotor hub assembly according to claim 1 wherein the constant velocity joint includes an tri-lobe trunnion that is engaged with the blade actuation shaft, a needle bearing is rotatably disposed about each lobe and engages with an inner surface on the outer housing.

7. A gimbaled rotor hub assembly according to claim 1 wherein the planetary gearset has a reduction ratio of about 6:20:1 and the lower hypoid bevel gear engagement with the output gear provides a reduction of about 3.58:1.

8. A rotor hub assembly for a variable diameter rotor system, the system including a plurality of rotor blade assemblies mounted to and rotated by the rotor hub assembly about an axis of rotation, each rotor blade assembly having an inboard blade section and an outboard blade section, the outboard blade section being telescopically mounted to the inboard blade section, each rotor blade assembly having a mass center, the system further including a jackscrew rotatably disposed within the rotor blade assembly and engaged with the outboard blade section for telescoping the outboard blade section with respect to the inboard blade section, the jackscrew having an output pinion located at its inboard end, the rotor hub assembly comprising:

- a main rotor shaft having an upper end and an axis of rotation;
- a rotor hub disposed about the upper end of the main rotor shaft, the blade assemblies being spaced about and attached to the rotor hub, the rotor hub having a pivot point located at the intersection of the axis of rotation and a line along the mass center of the rotor blade assemblies;
- a first elastomeric bearing disposed between and attached to the upper end of the main rotor shaft and the rotor hub;
- a second elastomeric bearing attached to the main rotor shaft and the rotor hub and located above the upper end of the rotor shaft;
- the first and second elastomeric bearings each having a substantially spherical shape and centers of curvature that substantially coincide with one another and the rotor hub pivot point at a location between the first and second elastomeric bearings;
- a blade actuation shaft concentrically disposed within the main rotor shaft, the blade actuation shaft having an upper end;
- a constant velocity joint pivotally attached to the upper end of the blade actuation shaft about the pivot point; and
- a planetary gearset located within the rotor hub assembly including
  - a sun gear attached to a housing above the second elastomeric bearing,
  - a plurality of pinion gears disposed about and intermeshing with the sun gear, the pinion gears being rotatably mounted to a pinion cage, the pinion cage being rotatably in contact with the rotor hub,

## 16

a lower hypoid bevel gear attached to the pinion gears and forms a ring within the rotor hub assembly, the lower hypoid bevel gear adapted to intermesh with the output pinion on the jackscrew, and

a ring gear located radially outward from and intermeshing with the pinion gears.

9. A gimbaled rotor hub assembly according to claim 8 further comprising a bearing support attached to the main rotor hub, and upper and lower bearing members attached to the rotor hub, wherein the first elastomeric bearing is sandwiched between the bearing support and the lower bearing member and the second elastomeric bearing is sandwiched between the bearing support and the upper bearing member.

10. A gimbaled rotor hub assembly according to claim 8 wherein the first and second elastomeric bearings include a plurality of elastomer layers interleaved with nonresilient shims.

11. A gimbaled rotor hub assembly according to claim 8 wherein the planetary gearset includes a movable ring gear which is intermeshed with the pinion gears, the lower hypoid bevel gear being fixedly attached to the movable ring gear, the pinion cage being rotatably supported by the housing, and wherein the first ring gear is fixedly attached to the rotor hub and meshes with a secondary pinion that is splined to the pinion gear.

12. A gimbaled rotor hub assembly according to claim 8 wherein the lower hypoid bevel gear is fixedly engaged with pinion cage such that rotation of the pinion cage by the pinions causes the lower hypoid bevel gear to rotate.

13. A gimbaled rotor hub assembly according to claim 8 wherein the constant velocity joint includes a tri-lobe trunnion that is engaged with the blade actuation shaft, a needle bearing is rotatably disposed about each lobe and engages with an inner surface on the outer housing.

14. A gimbaled rotor hub assembly according to claim 8 wherein the planetary gearset has a reduction ratio of about 6:20:1 and the lower hypoid bevel gear engagement with the output gear provides a reduction of about 3.58:1.

15. A variable diameter rotor system for an aircraft comprising

- a main rotor shaft having an upper end and having an axis of rotation;
- a plurality of rotor blade assemblies, each rotor blade assembly having an inner blade segment and an outer blade segment, the outer blade segment being telescopically mounted to the inner blade segment, each rotor blade assembly having a mass center;
- a jackscrew rotatably disposed within the rotor blade assembly and engaged with the outer blade segment for telescoping the outer blade segment with respect to the inner blade segment, the jackscrew having an output pinion located at its inboard end,
- a rotor hub having an axis of rotation and being pivotally mounted to the upper end of the main rotor shaft about a pivot point, the pivot point being located at the intersection of the rotor hub axis of rotation and a line along the mass center of the rotor blade assemblies, the inner blade segment of each rotor blade assembly being mounted to the rotor hub assembly such that the rotor blade assemblies are rotated by the rotor hub assembly about the rotor hub axis of rotation;
- a first elastomeric bearing disposed between and attached to an upper portion of the main rotor shaft and the rotor hub;
- a second elastomeric bearing attached to the main rotor shaft and the rotor hub;

## 17

the first and second elastomeric bearings permitting pivoting of the rotor hub about the pivot point with respect to the main rotor shaft while transmitting rotational loads therebetween;

- a blade actuation shaft concentrically disposed within the main rotor shaft, the blade actuation shaft having an upper end;
- a constant velocity joint pivotally attached to the upper end of the blade actuation shaft about the pivot point; and
- a planetary gearset located within the rotor hub and engaging the blade actuation shaft with the output pinion, the planetary gearset including
  - a sun gear attached to a housing above the second elastomeric bearing,
  - a fixed ring gear attached to the rotor hub and located radially out board from the sun gear, and
  - a plurality of pinion gears disposed between and intermeshing with the sun gear and the ring gear, the pinion gears being rotatably mounted to a pinion cage, the pinion cage being rotatable with respect to the housing and the fixed ring gear,
  - a lower hypoid bevel gear rotatably driven by the pinion gears and adapted to intermesh with the output pinion on the jackscrew.

**16.** A gimbaled rotor hub assembly according to claim **15** wherein the pivot point is located above the first elastomeric bearing and below the second elastomeric bearing, the rotor hub assembly further comprising a bearing support attached to the main rotor hub, and upper and lower bearing members attached to the rotor hub, wherein the first elastomeric bearing is sandwiched between the bearing support and the lower bearing member and the second elastomeric bearing is sandwiched between the bearing support and the upper bearing member.

**17.** A gimbaled rotor hub assembly according to claim **15** wherein the first and second elastomeric bearings include a plurality of elastomer layers interleaved with nonresilient shims.

**18.** A gimbaled rotor hub assembly according to claim **15** wherein the planetary gearset includes a movable ring gear

## 18

which is intermeshed with the pinion gears, the lower hypoid bevel gear being fixedly attached to the movable ring gear, the pinion cage being rotatably supported by the housing, and wherein the fixed ring gear is fixedly attached to the rotor hub and meshes with a secondary pinion that is splined to the pinion gear.

**19.** A gimbaled rotor hub assembly according to claim **15** wherein the lower hypoid bevel gear is fixedly engaged with pinion cage such that rotation of the pinion cage by the pinions causes the lower hypoid bevel gear to rotate.

**20.** A gimbaled rotor hub assembly according to claim **15** wherein the constant velocity joint includes an tri-lobe trunnion that is engaged with the blade actuation shaft, a needle bearing is rotatably disposed about each lobe and engages with an inner surface on the outer housing.

**21.** A gimbaled rotor hub assembly according to claim **15** wherein the planetary gearset has a reduction ratio of about 6:20:1 and the lower hypoid bevel gear engagement with the output gear provides a reduction of about 3.58:1.

**22.** A gimbaled rotor hub assembly according to claim **15** further comprising a locking mechanism mounted on each rotor blade assembly for locking the outer blade segment to the rotor hub.

**23.** A gimbaled rotor hub assembly according to claim **22** the locking mechanism including at least one pin which is engaged with an actuator, the actuator controlling engagement and of the pin, the locking mechanism mounted so as to permit engagement of the pin with a hole formed in the rotor blade hub when the outer blade segment is in a retracted position.

**24.** A gimbaled rotor hub assembly according to claim **15** further comprising a misalignment coupling mounted between the output pinion and the jackscrew for accommodating angular misalignment.

**25.** A gimbaled rotor hub assembly according to claim **15** further comprising a flexible elastomeric bearing support located between the jackscrew and the rotor hub for reducing bending loads on the jackscrew.
